Rx 8 BITS/CHAR

DO Receiver Enable--A one enables the receiver to begin. This bit should be set only after the receiver has been initialized.

Auto Enables--A one written to this bit caused CD to be auto-matic enable signal for the receiver and CTC to be an automatic enable signal for the transmitter. A zero written to this bit limits the effect of CD and CTS signals to setting/resetting their corresponding bits in the status register (RRO).

D7,D6 Receive Character length

O O Receive 5 Data bits/character

O 1 Receive 7 Data bits/character

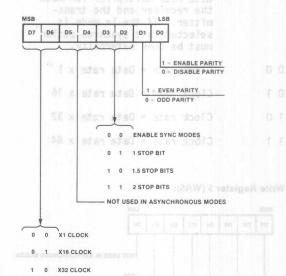

1 O Receive 6 Data bits/character

1 1 Receive 8 Data bits/character

2 is specified. This bit is always zero in Channel 8.

Transmit Buffer Empty--Ihis bit is set whenever the transmit buffer is empty except when CRC characters are being sent in a synchronous mode. This bit is reset when the transmit buffer is loaded. This bit is set after an MAPC reset.

## Write Register 4 (WR4): 192--- short short 3

Parity—a one in this bit causes a parity bit to be added to the programmed number of data bits per character for both the transmitted and received character. If the MPSC is programmed to receive 8 bits per character, the parity bit is not transferred to the microprocessor. With other receiver character lengths, the parity bit is transferred to the microprocessor.

D1 Even/Odd Parity -- if parity is enabled, a one in this bit causes the MPSC to transmit and expect even parity, and zero causes it to send and expect odd parity.

D3,D2 Stop Bits

1 X64 CLOCK

0 0 Selects synchronous modes.

0 1 Async mode, 1 stop bit/character

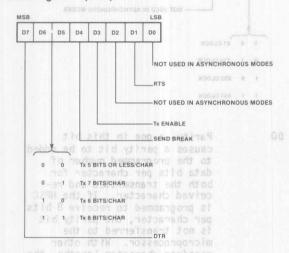

1 0 Async mode, 1-1/2 stop bits/ character

1 1 Async mode, 2 stop bits/character

AFN: 01995A

D7,D6	Clock modeselects the clock/ data rate multiplier for both the receiver and the trans- mitter. If the lx mode is selected, bit synchronization must be done externally.
0 0	Clock rate = Data rate x 1
0 1	Clock rate = Data rate x 16
1 0	Clock rate = Data rate x 32
11	Clock rate = Data rate x 64

#### Write Register 5 (WR5): 212 MOTES

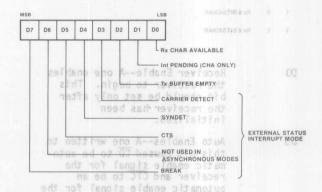

D1 Request to Send—a one in this bit forces the  $\overline{\text{RTS}}$  pin active (10w) and zero in this bit forces the  $\overline{\text{RTS}}$  pin inactive (high).

D3 Transmitter Enable—a zero in this bit forces a marking state on the transmitter output. If this bit is set to zero during data or sync character transmission, the marking state is entered after the character has been sent. If this bit is set to zero during transmission of a CRC character, sync or flag bits are substituted for the remainder of the CRC bits.

D4 Send Break--a one in this bit forces the transmit data low.
A one in this bit allows normal transmitter operation.

D6,D5	Transmit Character length	
0 0	Transmit 5 or less bits/ character	
0 1	Transmit 7 bits/character	
1 0	Transmit 6 bits/character	
11	Transmit 8 bits/character	
	sent must be right justified ificant bit first, eg:	
	4 D3 D2 D1 D0 4 B3 B2 B1 B0	

#### Read Register 0 (RR0):

DO Receive Character Available-this bit is set when the receive FIFO contains data and is proportion of the reset when the FIFO is empty.

Interrupt Pending—This Interrupt—Pending bit is reset when and EO1 command is issued and there is no other interrupt request pending at that time.

In vector mode this bit is set at the falling edge of the second INTA in an INTA cycle for an internal interrupt request. In non-vector mode, this bit is set at the falling edge of RD input after pointer 2 is specified. This bit is always zero in Channel B.

D2 Transmit Buffer Empty—This bit is set whenever the transmit buffer is empty except when CRC characters are being sent in a synchronous mode. This bit is reset when the transmit buffer is loaded. This bit is set after an MPSC reset.

etwalke made this bit is sat	tains the state of the CD pitains the		
D3	Carrier Detect This bit con-		
	tains the state of the CD pin	ceive mode, this bit	is setz di
	at the time of the last change	when a Break sequence	(nullective
	of any of the External/Status	character plus framin	g error)
	bits (CD, CTS, Sync/Hunt,	is detected in the da	ta berosal
	Break/Abort, or Tx Underrun/	stream. The External	
	EOM). Any change of state of	interrupt, if enabled	
	the CD pin causes the CD bit to	when break is detected	
	be latched and causes an Ex-	interrupt service rou	
1,000	ternal/Status interrupt. This	issue the Reset Exter	
	bit indicates current state of	Interrupt command (WR	
	the CD pin immediately follow-	2) to the break detec	tion logic
	ing a Reset External/Status	so the Break sequence	termina-
	Interrupt command.	end solition can be recognized	tosff bas

SYNDET -- In asynchronous modes. 00-70 D4 the operation of this bit is similar to the CD status bit, except that it shows the state of the SYNDET input. Any High-to-Low transition on the SYNDET pin sets this bit, and causes an External/Status interrupt (if enabled). The Reset External/Status Interrupt command is issued to clear the interrupt. A Low-to-High transition clears this bit and sets the External/Status interrupt. When the External/Status interrupt is set by the change in state of any other input or condition, this bit shows the inverted state of the SYNDET pin at time of the change. This bit must be read immediately following a Reset External/Status Interrupt command to read the current state of the SYNDET input.

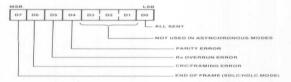

Clear to Send--this bit contains the inverted state of the CTS pin at the time of the last change of any of the External/ Status bits (CD, CTS, Sync/ Hunt, Break/Abort, or Tx Underrun/EOM). Any change of state of the CTS pin causes the CTS bit to be latched and causes an External/Status interrupt. This bit indicates the inverse of the current state of the CTS pin immediately following a Reset External/Status Interrupt command.

D5

.... DIE ASVACHIONOUS Break-in the ASVACHIONO

The Break bit is reset when the termination of the Break sequence is detected in the incoming data stream. The termination of the Break sequence also causes the External/Status interrupt to be set. The Reset External/Status Interrupt command must be issued to enable the break detection logic to look for the next Break sequence. A single extraneous null character is present in the receiver after the termination of a break: it should be read and discarded.

#### Read Register 1 (RR1)

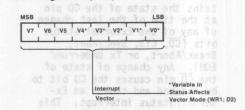

All sent -- this bit is set when all characters have been sent, in asynchronous modes. It is reset when characters are in the transmitter, in asynchronous modes. In synchronous modes, this bit is always set.

AFN: 01995A

- D4 Parity Error--If parity is enabled, this bit is set for received characters whose parity does not match the programmed sense (Even/Odd). This bit is latched. Once an error occurs, it remains set until the Error Reset command is written. I dans to diquired at
- D5 Receive Overrun Error--this bit indicates that the receive FIFO has been overloaded by the receiver. The last character in the FIFO is overwritten and flagged with this error. Once the overwritten character is read, this error condition is latched until reset by the Error Reset command. If the MPSC is in the status affects vector mode, the overrun causes a special Receive Error Vector.
- D6 Framing Error--In async modes, a one in this bit indicates a receive framing space error. It can be reset by issuing an Error Reset command. an ad b fuel at the sand

Read Register 2 (RR2): -- to at all the install

RR2

Channel B D7-D0 Interrupt vector--contains the interrupt vector programmed into WR2. If the status affects vector mode is selected, it contains the modified vector. (See WR2) RR2 contains the modified vector for the highest priority interrupt pending. If no interrupts are pending, the variable bits in the vector are set to one.

### Appendix D

### Application Example Using SDK-86

This application example shows the 8274 in simple iAPX-86/88 system. The 8274 controls two separate asynchronous channels using its internal interrupt controller to request all data transfers. The 8274 driver software is described which transmits and receives data buffers provided by the CPU. Also, status registers are maintained in system memory to allow the CPU to monitor progress of the buffers and error conditions.

### THE HARDWARE INTERFACE

Nothing could be easier than the hardware design of an interrupt-driven 8274 system. Simply connect the data bus lines, a few bus control lines, supply a timing clock for baud rate and, voila, it's done! For this example, the ubiquitous SDK-86 is used as the host CPU system. The 8274 interface is constructed on the wire-wrap area provided. While discussing the hardware interface, please refer to Diagram 1.

Placing the 8274 on the lower 8-bits of the 8086 data bus allows byte-wide data transfers at even I/O addresses. For simplicity, the 8274's CS/ input is generated by combining the M-IO/ select line with address line A7 via a 7432. This places the 8274 address range in multiple spots within the 8086 I/O address space. (While fine for this example, a more complete address decoding is recommended for actual prototype systems.) The 8086's Al and A2 address lines are connected to the AO and Al 8274 register select inputs respectively. Although other port assignments are possible because of the overlapping address spaces, the following I/O port assignments are used in this example:

| Port Function    | I/O Address |
|------------------|-------------|
| Data channel A   | 0000H       |
| Command/status A | 0002H       |
| Data channel B   | 0004H       |
| Command/status B | 000 6H      |

To connect the 8274's interrupt controller into the system an inverter and pull-up resistor are needed to convert the 8274's active-low interrupt request output, IRQ, into the correct polarity for the 8086's INTR interrupt input. The 8274 recognizes interrupt acknowledge bus cycles by connecting the INTA (INTerrupt Acknowledge) lines of the 8274 and 8086 together.

The 8274 ReaD and WRite lines directly connect to the respective 8086 lines. The RESET line requires an inverter. The system clock for the 8274 is provided by the PCLK (peripheral clock) output of the 8284A clock generator.

On the 8274's serial side, traditional 1488 and 1489 RS-232 drivers and receivers are used for the serial interface. The onboard baud rate generator supplies the channel baud rate timing. In this example, both sides of both channels operate at the same baud rate although this certainly is not a requirement. (On the SDK-86, the baud rate selection is hard-wired thru jumpers. A more flexible approach would be to incorporate a 8253 Programmable Interval Timer to allow software-configurable baud rate selection.)

That's all there is to it. This hardware interface is completely general-purpose and supports all of the 8274 features except the DMA data transfer mode which requires an external DMA controller. Now let's look at the software interface.

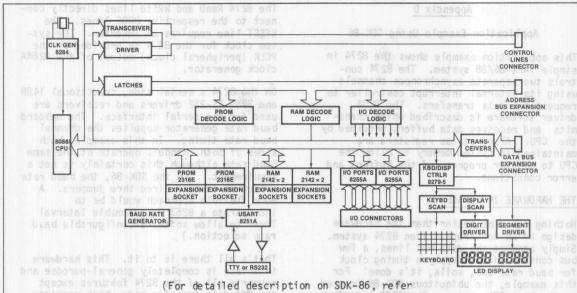

### SOFTWARE INTERFACE

In this example, it is assumed that the 8086 has better things to do rather than continuously run a serial channel. Presenting the software as a group of callable procedures lets the designer include them in the main body of another program. The interrupt-driven data transfers give the effect that the serial channels are handled in the background while the main program is executing in the foreground. There are five basic procedures: a serial channel initialization routine and buffer handling routines for the transmit and receive data buffers of each channel. Appendix D-1 shows the entire software listing. Listing line numbers are referenced as each major routing is discussed.

The channel initialization routine (INITIAL 8274), starting with line #203, simply sets each channel into a particular operating mode by loading the command registers of the 8274. In normal operation, once these registers are loaded, they are rarely changed. (Although this example assumes a simple asynchronous operating mode, the concept is easily extended for the byte and bit-sychronous modes.)

The channel operating modes are contained in two tables starting with line #163. As the 8274 has only one command register per channel, the remaining seven registers are

AFN: 01995A

(For detailed description on SDK-86, refer to upidu add signals and to SDK-86 MCS-86 System Design Kit Assembly Manual)

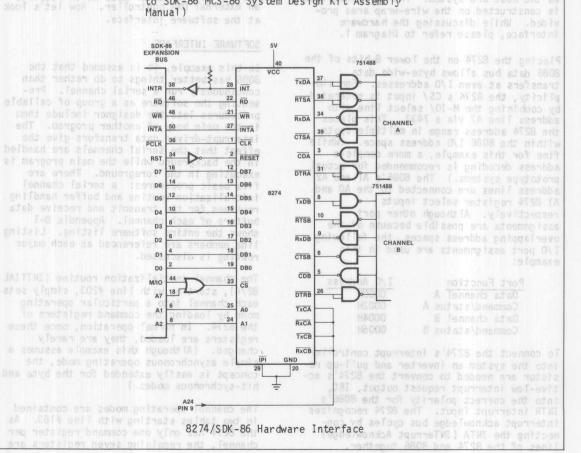

Diagram 1

loaded indirectly through the WRO (Write Register O) register. The first byte of each table entry is the register pointer value which is loaded into WRO and the second byte is the value for that particular register.

The indicated modes set the 8274 for asynchronous operation with data characters 8 bits long, no parity, and 2 stop bits. A X16 baud rate clock is assumend. Also selected is the "interrupt on all RX character" mode with a variable interrupt vector compatible with the 8086/8088. The transmitters are enabled and all model control lines are put in their active state.

In addition to initializing the 8274, this routine also sets up the appropriate interrupt vectors. The 8086 assumes the first 1K bytes of memory contain up to 256 separate interrupt vectors. On the SDK-86 the initial 2K bytes of memory is RAM and therefore must be initialized with the appropriate vectors. (In a prototype system, this initial memory is probably ROM thus the vector set-up is not needed.) The 8274 supplies up to eight different interrupt vectors. These vectors are developed from internal conditions such as data requests, status changes, or error conditions for each channel. The initialization routine arbitrarily assumes that the initial 8274 vector corresponds to 8086 vector location 80H (memory location 200H). This choice is arbitrary since the 8274 initial vector location is programmable.

Finally, the initialization routine sets up the status and flag in RAM. The meaning and use of these locations are discussed later.

Following the initialization routine are those for the transmit commands (starting with line #268). These commands assume that the host CPU has initialized the publically declared variables for the transmit buffer pointer, TX\_POINTER\_CHx, and the buffer length, TX\_LENGTH\_CHx. The transmit command routines simply clear the transmitter empty flag, TX EMPTY CHx, and load the first character of the buffer into the transmitter. It is necessary to load the first character in this manner since transmitter interrupts are generated only when the 8274's transmit data buffer becomes empty. It is the act of becoming empty which generates the interrupt not simply the buffer being empty, thus the transmitter needs one character to start.

The host CPU can monitor the transmitter empty flag, TX\_EMPTY\_CHx, in order to determine when transmission of the buffer is complete. Obviously, the CPU should only call the command routine after first checking that the empty flag is set.

After returning to the main program, all sell transmitter data transfers are handled via the transmitter interrupt service routines starting at lines #360 and #443. These routines start by issuing and End-Of-Interrupt command to the 8274. (This command resets the internal interrupt controller logic of the 8274 for this particular vector and opens the logic for other internal interrupt requests. The routines next check the length count. If the buffer is completely transmitted, the transmitter empty flag. TX EMPTY CHx. is set and a command is issued to the 8274 to reset its interrupt line. Assuming that the buffer is not completely transmitted, the next character is output to the transmitter. In either case, an interrupt return is executed to return to the main CPU program.

The receiver commands start at line #314. Like the transmit commands, it is assumed that the CPU has initialized the receive buffer pointer public variable, RX\_POINTER\_CHx. This variable points to the first location in an empty receive buffer. The command routines clear the receiver ready flag, RX\_READY\_CHx, and then set the receiver enable bit in the 8274 WR3 register. With the receiver now enabled, any received characters are placed in the receive buffer using interrupt-driven data transfers.

The received data service routines, starting at lines #402 and #485, simply place the received character in the buffer after first issuing the EOI command. The character is then compared to a ASCII CR. An ASCII CR causes the routine to set the receiver ready flag, RX\_READY\_CHx, and to disable the receiver. The CPU can interrogate this flag to determine when the buffer contains a new line of data. The receive buffer pointer, RX\_POINTER\_CHx, points to the last received character and the receive counter, RX\_COUNTER\_CHx, contains the length.

That completes our discussion of the command routines and their associated interrupt service routines. Although not used by the commands, two additional service routines are included for completeness. These routines handle the error and status-change interrupt vectors.

The error service routines, starting at lines #427 and #510, are vectored to if a special receive condition is detected by the 8274. These special receive conditions include parity, receiver overrun, and framing errors. When this vector is generated, the error condition is indicated in RRI (Read Register 1). The error service routine issues an EOI command, reads RRI and places it in the ERROR\_MSG\_CHx variable, and then issues a reset error command to the 8274. The CPU can monitor the error message location to detect error conditions. The designer, of course, can supply his own error service routine.

Similarily, the status-change routines (starting lines #386 and #469) are initiated by a change in the modem control status lines CTS/, CD/, or SYNDET/. (Note that WR2 bit 0 controls whether the 8274

generates interrupts based upon changes in these lines. Our WR2 parameter is such that the 8274 is programmed to ignore changes for these inputs.) The service routines simply read RRO, place its contents in the STATUS\_MSG\_CHx variable and then issue a reset external status command. Read Register O contains the state of the modem inputs at the point of the last change.

Well, that's it. This application example has presented useful, abeit very simple, routines showing how the 8274 might be used to transmit and recieve buffers using an asynchronous serial format. Extensions for byte or bit-synchronous formats would require no hardware changes due to the highly programmable nature of the 8294's serial formats.

### INTRODUCTION

The Intel® 8292 is a preprogrammed UPI™-41A that implements the Controller function of the IEEE Std 488-1978 (GPIB, HP-IB, IEC Bus, etc.). In order to function the 8292 must be used with the 8291 ceiver logic such as a pair of Intel 8293s. In this configuration the system has the potential to be a so complete GPIB Controller when driven by the appropriate software. It has the following capa- 8847 bilities: System Controller, send IFC and Take Charge, send REN, Respond to SRO, send Interface messages, Receive Control, Pass Control, Parallel Poll and Take Control Synchronously. Raving 39AW

This application note will explain the 8292 only in the system context of an 8292, 8291, two 8293s and the driver software. If the reader wishes to learn more about the UPI-41A aspects of the 8292, Intel's Application Note AP-41 describes the hardware and a second features and programming characteristics of the louing device. Additional information on the 8291 may be applied obtained in the data sheet. The 8293 is detailed in its data sheet. Both chips will be covered here in the details that relate to the GPIB controller.

The next section of this application note presents an overview of the GPIB in a tutorial, but comprehensive nature. The knowledgable reader may wish to skip this section; however, certain basic semantic concepts introduced there will be used throughout soon this note.

Additional sections cover the view of the 8292 from the CPU's data bus, the interaction of the 3 chip types (8291, 8292, 8293), the 8292's software protocol and the system level hardware/software protocol. A brief description of interrupts and DMA will be followed by an application example. Appendix A contains the source code for the system and tance interconnections. driver software.

## **GPIB/IEEE 488 OVERVIEW**

### **DESIGN OBJECTIVES**

### What is the IEEE 488 (GPIB)?

The experience of designing systems for a variety of applications in the early 1970's caused Hewlett-Packard to define a standard intercommunication mechanism which would allow them to easily assemble instrumentation systems of varying degrees of complexity. In a typical situation each instrument designer designed his/her own interface from scratch. Each one was inconsistent in terms of electrical levels, pin-outs on a connector, and types of connectors. Every time they built a system they had to invent new cables and new documentation just to specify the cabling and interconnection procedures.

Based on this experience, Hewlett-Packard began to define a new interconnection scheme. They went further than that, however, for they wanted to specify the typical communication protocol for systems of instruments. So in 1972, Hewlett-Talker/Listener and suitable interface and transwhich since has been modified and standardized by a committee of several manufacturers, coordinated through the IEEE, to perfect what is now known as the IEEE 488 Interface Bus (also known as the HP-IB, the GPIB and the IEC bus). While this bus specification may not be perfect, it is a good compromise of the various desires and goals of instrumentation and computer peripheral manufacturers to produce a common interconnection mechanism. It fits most instrumentation systems in use today and also fits very well the microcomputer I/O bus requirements. The basic design objectives for the GPIB were to:

- 1. Specify a system that is easy to use, but has all of the terminology and the definitions related to that system precisely spelled out so that everyone uses the same language when discussing the GPIB.
- 2. Define all of the mechanical, electrical, and functional interface requirements of a system, yet not define any of the device aspects (they are left up to the instrument designer).
- 3. Permit a wide range of capabilities of instruments and computer peripherals to use a system simultaneously and not degrade each other's per-ARETMI formance.
  - 4. Allow different manufacturers' equipment to be connected together and work together on the
  - 5. Define a system that is good for limited dis-
- epoliteid source 6. Define a system with minimum restrictions on performance of the devices.
  - a xiguage 7. Define a bus that allows asynchronous communication with a wide range of data rates.
  - 8. Define a low cost system that does not require OXIGNASSA extensive and elaborate interface logic for the low cost instruments, yet provides higher capability for the higher cost instruments if desired.
    - 9. Allow systems to exist that do not need a central controller; that is, communication directly from one instrument to another is possible.

Although the GPIB was originally designed for instrumentation systems, it became obvious that most of these systems would be controlled by a calculator or computer. With this in mind several modifications were made to the original proposal before its final adoption as an international standard. Figure 1 lists the salient characteristics of the

The bus can be best understood by examining each of these characteristics from the viewpoint of a general microcomputer I/O bus.

Data Rate - Most microcomputer systems utilize peripherals of differing operational rates, such as floppy discs at 31k or 62k bytes/s (single or double density), tape cassettes at 5k to 10k bytes/s, and cartridge tapes at 40k to 80k bytes/s. In general, the only devices that need high speed I/O are 0.5" (1.3cm) magnetic tapes and hard discs, operational at 30k to 781k bytes/s, respectively. Certainly, the 250k-bytes/s data rate that can be easily achieved by the IEEE 488 bus is sufficient for microcomputers and their peripherals, and is more than needed for typical analog instruments that take only a few readings per second. The 1M-byte/s maximum data rate is not easily achieved on the GPIB and requires special attention to considerations beyond the scope of this note. Although not required, data buffering in each device will improve the overall bus performance and allow utilization of more of the bus poll capability in the IEEE 488 allows htbiwbned

Multiple Devices — Many microcomputer systems used as computers (not as components) service from three to seven peripherals. With the GPIB, up to 8 devices can be handled easily by 1 controller; with some slowdown in interrupt handling, up to 15 devices can work together. The limit of 8 is imposed by the number of unique parallel poll responses available; the limit of 15 is set by the electrical drive characteristics of the bus. Logically, the IEEE 488 Standard is capable of accommodating more device addresses (31 primary, each potentially with 31 secondaries), it this With the can be obtained using DMA. With the

Bus Length — Physically, the majority of microcomputer systems fit easily on a desk top or in a standard 19" (48-cm) rack, eliminating the need for extra long cables. The GPIB is designed typically to have 2 m of length per device, which accommodates most systems. A line printer might require greater cable lengths, but this can be handled at the lower speeds involved by using extra dummy terminaon the bus by allowing each device to transfer agnoit

Byte Oriented — The 8-bit byte is almost universal in I/O applications; even 16-bit and 32-bit computers use byte transfers for most peripherals. The 8bit byte matches the ASCII code for characters and is an integral submultiple of most computer word sizes. The GPIB has an 8-bit wide data path that may be used to transfer ASCII or binary data, as well as the necessary status and control bytes.

Block Multiplexed — Many peripherals are block oriented or are used in a block mode. Bytes are transferred in a fixed or variable length group; then there is a wait before another group is sent to that device, e.g., one sector of a floppy disc, one line on a printer or tape punch, etc. The GPIB is, by nature, a block multiplexed bus due to the overhead involved in addressing various devices to talk and listen. This overhead is less bothersome if it only occurs once for a large number of data bytes (once per block). This mode of operation matches the needs of microcomputers and most of their peripherals. Because of block multiplexing, the bus works best with buffered memory devices.

Interrupt Driven — Many types of interrupt systems exist, ranging from complex, fast, vectored/priority networks to simple polling schemes. The main tradeoff is usually cost versus speed of response. The GPIB has two interrupt protocols to help span the range of applications. The first is a single service request (SRQ) line that may be asserted by all interrupting devices. The controller then polls all devices to find out which wants service. The polling mechanism is well defined and can be easily

automated. For higher performance, the parallel poll capability in the IEEE 488 allows up to eight devices to be polled at once — each device is assigned to one bit of the data bus. This mechanism provides fast recognition of an interrupting device. A drawback is the frequent need for the controller to explicitly conduct a parallel poll, since there is no equivalent of the SRQ line for this mode.

Direct Memory Access (DMA) — In many applications, no imediate processing of I/O data on a byte-by-byte basis is needed or wanted. In fact, programmed transfers slow down the data transfer rate unnecessarily in these cases, and higher speed can be obtained using DMA. With the GPIB, one DMA facility at the controller serves all devices. There is no need to incorporate complex logic in each device.

Asynchronous Transfers — An asynchronous bus is desirable so that each device can transfer at its own rate. However, there is still a strong motivation to buffer the data at each device when used in large systems in order to speed up the aggregate data rate on the bus by allowing each device to transfer at top speed. The GPIB is asynchronous and uses a special

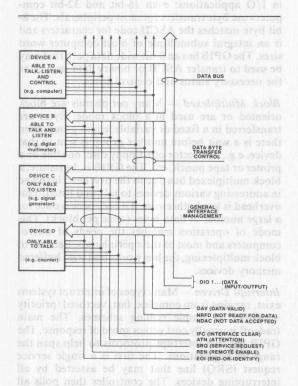

Figure 2. Interface Capabilities and Bus Structure

3-wire handshake that allows data transfers from one talker to many listeners.

I/O To I/O Transfers — In practice, I/O to I/O transfers are seldom done due to the need for processing data and changing formats or due to mismatched data rates. However, the GPIB can support this mode of operation where the microcomputer is neither the talker nor one of the listeners.

### GPIB SIGNAL LINES

### Data Bus

The lines DI01 through DI08 are used to transfer addresses, control information and data. The formats for addresses and control bytes are defined by the IEEE 488 standard (see Appendix C). Data formats are undefined and may be ASCII (with or without parity) or binary. DI01 is the Least Significant Bit (note that this will correspond to bit 0 on most computers).

## Management Bus was recent line listers

ATN — Attention This signal is asserted by the Controller to indicate that it is placing an address or control byte on the Data Bus. ATN is de-asserted to allow the assigned Talker to place status or data on the Data Bus. The Controller regains control by reasserting ATN; this is normally done synchronously with the handshake to avoid confusion between control and data bytes.

EOI — End or Identify This signal has two uses as its name implies. A talker may assert EOI simultaneously with the last byte of data to indicate end of data. The Controller may assert EOI along with ATN to initiate a Parallel Poll. Although many devices do not use Parallel Poll, all devices should use EOI to end transfers (many currently available ones do not).

SRQ — Service Request This line is like an interrupt: it may be asserted by any device to request the Controller to take some action. The Controller must determine which device is asserting SRQ by conducting a Serial Poll at its earliest convenience. The device deasserts SRQ when polled.

IFC — Interface Clear This signal is asserted only by the System Controller in order to initialize all device interfaces to a known state. After deasserting IFC, the System Controller is the active controller of the system.

REN — Remote Enable This signal is asserted only by the System Controller. Its assertion does not place devices into Remote Control mode; REN only enables a device to go remote when addressed to listen. When in Remote, a device should ignore its front panel controls.

## Transfer Busing a data for a data from Transfer Busing and Transfe

NRFD — Not Ready For Data This handshake line is asserted by a listener to indicate it is not yet ready for the next data or control byte. Note that the Controller will not see NRFD deasserted (i.e., ready for data) until all devices have deasserted NRFD.

NDAC — Not Data Accepted This handshake line is asserted by a Listener to indicate it has not yet accepted the data or control byte on the DIO lines. Note that the Controller will not see NDAC deasserted (i.e., data accepted) until all devices have deasserted NDAC.

DAV — Data Valid This handshake line is asserted by the Talker to indicate that a data or control byte has been placed on the DIO lines and has had the minimum specified settling time.

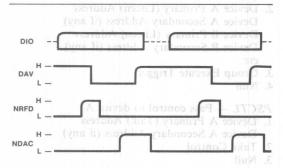

Figure 3. GPIB Handshake Sequence

### **GPIB INTERFACE FUNCTIONS**

There are ten (10) interface functions specified by the IEEE 488 standard. Not all devices will have all functions and some may only have partial subsets. The ten functions are summarized below with the relevant section number from the IEEE document given at the beginning of each paragraph. For further information please see the IEEE standard.

- SH Source Handshake (section 2.3) This function provides a device with the ability to properly transfer data from a Talker to one or more Listeners using the three handshake lines.
- AH Acceptor Handshake (section 2.4) This
  function provides a device with the ability to
  properly receive data from the Talker using the
  three handshake lines. The AH function may
  also delay the beginning (NRFD) or end
  (NDAC) of any transfer.
- T Talker (section 2.5) This function allows a device to send status and data bytes when addressed to talk. An address consists of one (Primary) or two (Primary and Secondary)

- bytes. The latter is called an extended Talker.
- L Listener (section 2.6) This function allows a device to receive data when addressed to listen. There can be extended Listeners (analogous to extended Talkers above).
- SR Service Request (section 2.7) This function allows a device to request service (interrupt) the Controller. The SRQ line may be asserted asynchronously.
- RL Remote Local (section 2.8) This function allows a device to be operated in two modes: Remote via the GPIB or Local via the manual front panel controls.
- PP Parallel Poll (section 2.9) This function allows a device to present one bit of status to the Controller-in-charge. The device need not be addressed to talk and no handshake is required.
- 8. DC Device Clear (section 2.10) This function allows a device to be cleared (initialized) by the Controller. Note that there is a difference between DC (device clear) and the IFC line (interface clear).
- 9. DT Device Trigger (section 2.11) This function allows a device to have its basic operation started either individually or as part of a group.

  This capability is often used to synchronize several instruments.
- 10. C Controller (section 2.12) This function allows a device to send addresses, as well as universal and addressed commands to other devices. There may be more than one controller on a system, but only one may be the controller-in-charge at any one time.

At power-on time the controller that is handwired to be the System Controller becomes the active controller-in-charge. The System Controller has several unique capabilities including the ability to send Interface Clear (IFC — clears all device interfaces and returns control to the System Controller) and to send Remote Enable (REN — allows devices to respond to bus data once they are addressed to listen). The System Controller may optionally Pass Control to another controller, if the system software has the capability to do so.

### GPIB CONNECTOR

The GPIB connector is a standard 24-pin industrial connector such as Cinch or Amphenol series 57 Micro-Ribbon. The IEEE standard specifies this connector, as well as the signal connections and the mounting hardware.

The cable has 16 signal lines and 8 ground lines. The maximum length is 20 meters with no more than two meters per device.

AFN-01380A

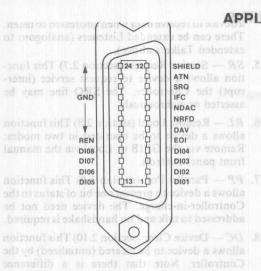

Figure 4. GPIB Connector

## GPIB SIGNAL LEVELS SOLVED A SWOTE HOLD

The GPIB signals are all TTL compatible, low true signals. A signal is asserted (true) when its electrical voltage is less than 0.5 volts and is deasserted (false) when it is greater than 2.4 volts. Be careful not to become confused with the two handshake signals, NRFD and NDAC which are also low true (i.e. > 0.5 volts implies the device is Not Ready For Data).

The Intel 8293 GPIB transceiver chips ensure that all relevant bus driver/receiver specifications are met. Detailed bus electrical specifications may be found in Section 3 of the IEEE Std 488-1978. The Standard is the ultimate reference for all GPIB questions.

## GPIB MESSAGE PROTOCOLS

The GPIB is a very flexible communications medium and as such has many possible variations of protocols. To bring some order to the situation, this section will discuss a protocol similar to the one used by Ziatech's ZT80 GPIB controller for Intel's MULTIBUS™ computers. The ZT80 is a complete high-level interface processor that executes a set of high level instructions that map directly into GPIB actions. The sequences of commands, addresses and data for these instructions provide a good example of how to use the GPIB (additional information is available in the ZT80 Instruction Manual). The 'null' at the end of each instruction is for cosmetic use to remove previous information from the DIO lines.

## HARDWARE ASPECTS OF THE SYSTEM

### 8291 GPIB TALKER/LISTENER 884 FIRST odd

The 8291 is a custom designed chip that implements many of the non-controller GPIB functions. It provides hooks so the user's software can implement additional features to complete the set. This chip is discussed in detail in its data sheet. The major features are summarized here; news noiseologis aids al

—Designed to interface microprocessors to the GPIB

—Complete Source and Acceptor Handshake

—Complete Talker and Listener Functions with extended addressing

-Service Request, Parallel Poll, Device Clear, Device Trigger, Remote/Local functions

Programmable data transfer rate

Maskable interrupts

On-chip primary and secondary address recogni-

1-8 MHz clock range

-16 registers (8 read, 8 write) for CPU interface

-DMA handshake provision

—Trigger output pin

On-chip EOS (End of Sequence) recognition

The pinouts and block diagram are shown in Fig. 5. One of eight read registers is for data transfer to the CPU; the other seven allow the microprocessor to monitor the GPIB states and various bus and device conditions. One of the eight write registers is for data transfer from the CPU; the other seven control various features of the 8291.

The 8291 interface functions will be software configured in this application example to the following subsets for use with the 8292 as a controller that does not pass control. The 8291 is used only to provide the handshake logic and to send and receive data bytes. It is not acting as a normal device in this mode, as it never sees ATN asserted.

| SHI                 | Source Handshake moississib tetal         |
|---------------------|-------------------------------------------|
|                     | Acceptor Handshake As as a Secretary      |
| T3 <sub>iomem</sub> | Basic Talk-only nos 1 UTO metava nism     |
| Lianthov            | Basic Listen-only                         |
| SR0                 | No Service Requests 190 dily betalooms    |
| RLO                 | No Remote/Local MAN gids                  |
| PPO SV S            | No Parallel Poll response of and to state |
| DC0                 | No Device Clear world and singly land to  |
| DT0                 | No Device Trigger and saff moderntolaid   |
|                     |                                           |

If control is passed to another controller, the 8291 must be reconfigured to act as a talker/listener with the following subsets:

Source Handshake SH1 AHI Acceptor Handshake Basic Talker and Serial Poll T5, bas y Basic Listener engal (A14-1910) COCS L3 Service Requests SRI Remote/Local with Lockout PP2 Preconfigured Parallel Poll information to the master Clear Device Clear DTI to am Device Trigger at Tutalizant TUOSSO affi CO and Not a Controller to abrow strike and to

Most applications do not pass control and the controller is always the system controller (see 8292 commands below). A series 198018100 1981 10113 Counter Status or Time Out Status

implement a GPIB controller when used with an 8291 Talker/Listener. The 8041A is documented in both a user's manual and in AP-41. The following description will serve only as an outline to guide the later discussion.

21 RS0

conditions. Or ear the eights

transfer from the CPU

The 8292 acts as an intelligent slave processor to the main system CPU. It contains a processor, memory, I/O and is programmed to perform a variety of tasks associated with GPIB controller operation. The onchip RAM is used to store information about the state of the Controller function, as well as a variety of local variables, the stack and certain user status information. The timer/counter may be optionally used for several time-out functions or for counting data bytes transferred. The I/O ports provide the GPIB control signals, as well as the ancillary lines necessary to make the 8291, 2, 3 work together.

The 8292 is closely coupled to the main CPU through three on-chip registers that may be independently accessed by both the master and the 8292 (UPI-41A). Figure 6 shows this Register Interface. Also refer to Figure 12.

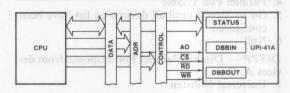

The status register is used to pass Interrupt Status information to the master CPU (A0 = 1 on a read).

The DBBOUT register is used to pass one of five other status words to the master based on the last command written into DBBIN. DBBOUT is accessed when A0 = 0 on a Read. The five status words are Error Flag, Controller Status, GPIB Status, Event Counter Status or Time Out Status.

DBBIN receives either commands (A0 = 1 on a Write) or command related data (A0 = 0 on a write) from the master. These command related data are Interrupt Mask, Error Mask, Event Counter or Time Out.

Figure 6. UPI-41A Registers

#### 8293 GPIB TRANSCEIVERS

The 8293 is a multi-use HMOS chip that implements the IEEE 488 bus transceivers and contains the additional logic required to make the 8291 and 8292 work together. The two option strapping pins are used to internally configure the chip to perform the specialized gating required for use with 8291 as a device or with 8291/92 as a controller.

In this application example the two configurations used are shown in Fig. 7a and 7b. The drivers are set to open collector or three state mode as required and the special logic is enabled as required in the two modes.

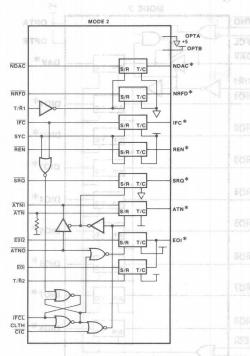

Figure 7a. 8293 Mode 2

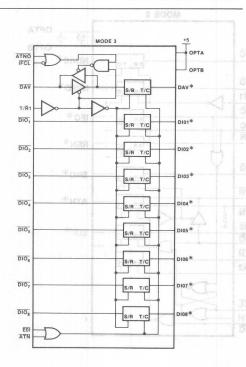

Figure 7b. 8293 Mode 3

### 8291/2/3 CHIP SET

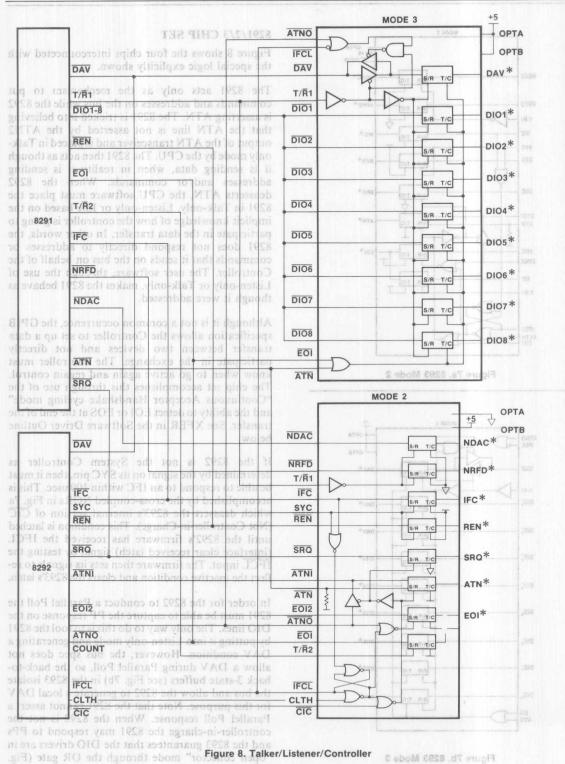

Figure 8 shows the four chips interconnected with the special logic explicitly shown.

The 8291 acts only as the mechanism to put commands and addresses on the bus while the 8292 is asserting ATN. The 8291 is tricked into believing that the ATN line is not asserted by the ATN2 output of the ATN transceiver and is placed in Talkonly mode by the CPU. The 8291 then acts as though it is sending data, when in reality it is sending addresses and/or commands. When the 8292 deasserts ATN, the CPU software must place the 8291 in Talk-only, Listen-only or Idle based on the implicit knowledge of how the controller is going to participate in the data transfer. In other words, the 8291 does not respond directly to addresses or commands that it sends on the bus on behalf of the Controller. The user software, through the use of Listen-only or Talk-only, makes the 8291 behave as though it were addressed.

Although it is not a common occurrence, the GPIB specification allows the Controller to set up a data transfer between two devices and not directly participate in the exchange. The controller must know when to go active again and regain control. The chip set accomplishes this through use of the "Continuous Acceptor Handshake cycling mode" and the ability to detect EOI or EOS at the end of the transfer. See XFER in the Software Driver Outline below.

If the 8292 is not the System Controller as determined by the signal on its SYC pin, then it must be able to respond to an IFC within 100 usec. This is accomplished by the cross-coupled NORs in Fig. 7a which deassert the 8293's internal version of CIC (Not Controller-in-Charge). This condition is latched until the 8292's firmware has received the IFCL (interface clear received latch) signal by testing the IFCL input. The firmware then sets its signals to reflect the inactive condition and clears the 8293's latch.

In order for the 8292 to conduct a Parallel Poll the 8291 must be able to capture the PP response on the DIO lines. The only way to do this is to fool the 8291 by putting it into Listen-only mode and generating a DAV condition. However, the bus spec does not allow a DAV during Parallel Poll, so the back-to-back 3-state buffers (see Fig. 7b) in the 8293 isolate the bus and allow the 8292 to generate a local DAV for this purpose. Note that the 8291 cannot assert a Parallel Poll response. When the 8292 is not the controller-in-charge the 8291 may respond to PPs and the 8293 guarantees that the DIO drivers are in "open collector" mode through the OR gate (Fig. 7b).

2-365

Figure 7b. 8293 Mode 3

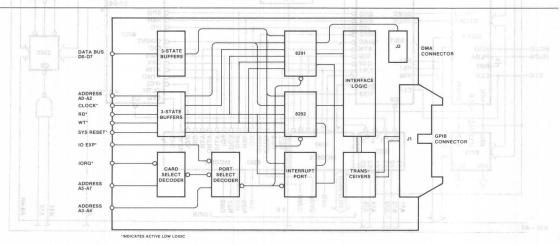

### **ZT7488/18 GPIB CONTROLLER**

Ziatech's GPIB Controller, the ZT7488/18 will be used as the controller hardware in this Application Note. The controller consists of an 8291, 8292, an 8 bit input port and TTL logic equivalent to that shown in Figure 8. Figure 9 shows the card's block diagram. The ZT7488/18 plugs into the STD bus, a 56 pin 8 bit microprocessor oriented bus. An 8085 CPU card is also available on the STD bus and will be used to execute the driver software.

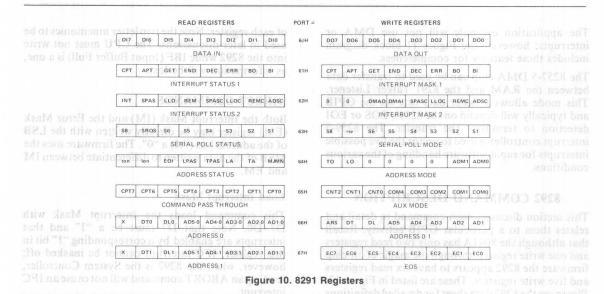

The 8291 uses I/O Ports 60H to 67H and the 8292 uses I/O Ports 68H and 69H. The five interrupt lines are connected to a three-state buffer at I/O Port

6FH to facilitate polling operation. This is required for the TCI, as it cannot be read internally in the 8292. The other three 8292 lines (SPI, IBF, OBF) and the 8291's INT line are also connected to minimize the number of I/O reads necessary to poll the devices.

NDAC is connected to COUNT on the 8292 to allow byte counting on data transfers. The example driver software will not use this feature, as the software is simpler and faster if an internal 8085 register is used for counting in software.

mangsi G Figure 9. ZT7488/18 GPIB Controller

2-366

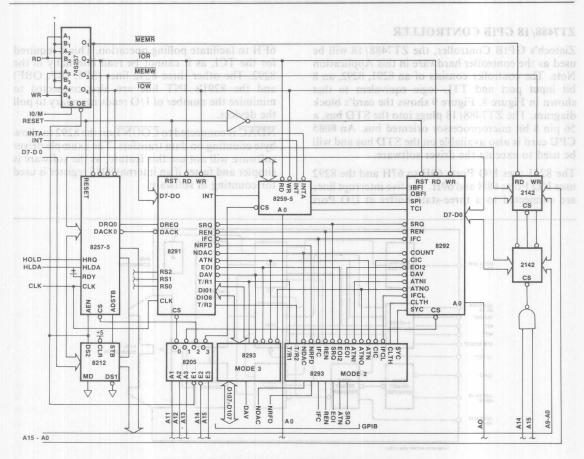

Figure 11. DMA/Interrupt GPIB Controller Block Diagram

The application example will not use DMA or interrupts; however, the Figure 11 block diagram includes these features for completeness.

The 8257-5 DMA chip can be used to transfer data between the RAM and the 8291 Talker/Listener. This mode allows a faster data rate on the GPIB and typically will depend on the 8291's EOS or EOI detection to terminate the transfer. The 8259-5 interrupt controller is used to vector the five possible interrupts for rapid software handling of the various conditions.

### 8292 COMMAND DESCRIPTION

This section discusses each command in detail and relates them to a particular GPIB activity. Recall that although the 8041A has only two read registers and one write register, through the magic of on-chip firmware the 8292 appears to have six read registers and five write registers. These are listed in Figure 12. Please see the 8292 data sheet for detailed definitions

of each register. Note the two letter mnemonics to be used in later discussions. The CPU must not write into the 8292 while IBF (Input Buffer Full) is a one, as information will be lost.

#### DIRECT COMMANDS

Both the Interrupt Mask (IM) and the Error Mask (EM) register may be directly written with the LSB of the address bus (A0) a "0". The firmware uses the MSB of the data written to differentiate between IM and EM.

### Load Interrupt Mask

This command loads the Interrupt Mask with D7-D0. Note that D7 must be a "1" and that interrupts are enabled by a corresponding "1" bit in this register. IFC interrupt cannot be masked off; however, when the 8292 is the System Controller, sending an ABORT command will not cause an IFC interrupt.

RIVM — Read Interrupt Mask Register stational September 12.829 September 10 the corresponding bit in the Interrupt Status Register. The command

## Load Error Mask selection acknowledge skeM rorr back

This command loads the Error Mask with D7-D0. Note that D7 must be a zero and that interrupts are enabled by a corresponding "1" bit in this register.

## UTILITY COMMANDS AMMOD KOITARISO

These commands are used to read or write the 8292 registers that are not directly accessible. All utility commands are written with A0 = 1, D7 = D6 = D5 = 1, D4 = 0. D3 - D0 specify the particular command. For writing into registers the general sequence is:

- 1. wait for IBF = 0 in Interrupt Status Register
- 2. write the appropriate command to the 8292,
- 3. write the desired register value to the 8292 with A0 = 1 with no other writes intervening.
- 4. wait for indication of completion from 8292 (IBF = 0).

For reading a register the general sequence is:

- 1. wait for IBF = 0 in Interrupt Status Register
- 2. write the appropriate command to the 8292
- 3. wait for a TCI (Task Complete Interrupt)
- 4. Read the value of the accessed register from the 8292 with A0 = 0.

WEVC — Write to Event Counter (Command = 0E2H)

The byte written following this command will be loaded into the event counter register and event counter status for byte counting. The internal

counter is incremented on a high to low transition of the COUNT (T1) input. In this application example NDAC is connected to count. The counter is an 8 bit register and therefore can count up to 256 bytes (writing 0 to the EC implies a count of 256). If longer blocks are desired, the main CPU must handle the interrupts every 256 counts and carefully observe the timing constraints.

Because the counter has a frequency range from 0 to 133 kHz when using a 6 MHz crystal, this feature may not be usable with all devices on the GPIB. The 8291 can easily transfer data at rates up to 250 kHz and even faster with some tuning of the system. There is also a 500 ns minimum high time requirement for COUNT which can potentially be violated by the 8291 in continuous acceptor handshake mode (i.e., TNDDV1 + TDVND2-C = 350 + 350 = 700 max). When cable delays are taken into consideration, this problem will probably never occur.

When the 8292 has completed the command, IBF will become a "0" and will cause an interrupt if masked on.

WTOUT — Write to Time Out Register (Command = 0E1H)

The byte written following this command will be used to determine the number of increments used for the time out functions. Because the register is 8 bits, the maximum time out is 256 time increments. This

OPIB but is not enough for a manually stepped operation using a GPIB logic analyzer like Ziatech's ZT488. Also, the 488 Standard does not set a lower limit on how long a device may take to do each action. Therefore, any use of a time out must be able to be overridden (this is a good general design rule for service and debugging considerations).

The time out function is implemented in the 8292's firmware and will not be an accurate time. The counter counts backwards to zero from its initial value. The function may be enabled/disabled by a bit in the Error mask register. When the command is complete IBF will be set to a "0" and will cause an interrupt if masked on.

REVC — Read Event Counter Status (Command = 0E3H)

This command transfers the content of the Event Counter to the DBBOUT register. The firmware then sets TCI = 1 and will cause an interrupt if masked on. The CPU may then read the value from the 8292 with A0 = 0.

RINM — Read Interrupt Mask Register (Command = 0E5H)

This command transfers the content of the Interrupt Mask register to the DBBOUT register. The firmware sets TCI = 1 and will cause an interrupt if masked on. The CPU may then read the value.

RERM — Read Error Mask Register (Command = 0EAH)

This command transfers the content of the Error Mask register to the DBBOUT register. The firmware sets TCI = 1 and will cause an interrupt if masked on. The CPU may then read the value.

RCST — Read Controller Status Register (Command = 0E6H)

This command transfers the content of the Controller Status register to the DBBOUT register. The firmware sets TCI = 1 and will cause an interrupt if masked on. The CPU may then read the value.

RTOUT — Read Time Out Status Register (Command = 0E9H)

This command transfers the content of the Time Out Status register to the DBBOUT register. The firmware sets TCI = 1 and will cause an interrupt if masked on. The CPU may then read the value.

If this register is read while a time-out function is in process, the value will be the time remaining before time-out occurs. If it is read after a time-out, it will be zero. If it is read when no time-out is in process, it will be the last value reached when the previous timing occurred.

(Command = UE/H) Are 1909 Harrier

This command causes the firmware to read the GPIB management lines, DAV and the SYC pin and place a copy in DBBOUT. TCI is set to "1" and will cause an interrupt if masked on. The CPU may read the value.

RERF — Read Error Flag Register (Command = 0E4H)

This command transfers the content of the Error Flag register to the DBBOUT register. The firmware sets TCI = I and will cause an interrupt if masked on. The CPU may then read the value.

This register is also placed in DBBOUT by an IACK command if ERR remains set. TCI is set to "1" in this case also

IACK — Interrupt Acknowledge (Command = A1 A2 A3 A4 1 A5 1 1)

This command is used to acknowledge any combinations of the five SPI interrupts (A1-A5): SYC, ERR, SRQ, EV, and IFCR. Each bit A1-A5 is an individual acnowledgement to the corresponding bit in the Interrupt Status Register. The command clears SPI but it will be set again if all of the pending interrupts were not acknowledged.

If A2 (ERR) is "1", the Error Flag register is placed in DBBOUT and TCI is set. The CPU may then read the Error Flag without issuing an RERF command.

### **OPERATION COMMANDS**

The following diagram (Fig. 13) is an attempt to show the interrelationships among the various 8292 Operation Commands. It is not meant to replace the complete controller state diagram in the IEEE Standard.

RST — Reset (Command = 0F2H)

This command has the same effect as an external reset applied to the chip's pin #4. The 8292's actions are:

- All outputs go to their electrical high state. This
  means that SPI, TCI, OBFI, IBFI, CLTH will be
  TRUE and all other GPIB signals will be FALSE.
- 2. The 8292's firmware will cause the above mentioned five signals to go FALSE after approximately 17.5 usec. (at 6 MHz).
- 3. These registers will be cleared: Interrupt Status, Interrupt Mask, Error Mask, Time Out, Event Counter, Error Flag.
- 4. If the 8292 is the System Controller (SYC is TRUE), then IFC will be sent TRUE for approximately 100 usec and the Controller function will end up in charge of the bus. If the 8292 is not the

AFN-01380A

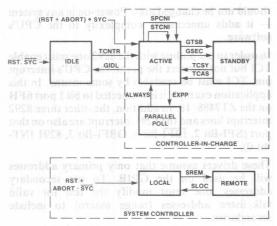

Figure 13. 8292 Command Flowchart

System Controller then it will end up in an Idle state.

5. TCI will not be set.

RSTI — Reset Interrupts (Command = 0F3)

This command clears all pending interrupts and error flags. The 8292 will stop waiting for actions to occur (e.g., waiting for ATN to go FALSE in a TCNTR command or waiting for the proper handshake state in a TCSY command). TCI will not be set.

ABORT — Abort all operations and Clear Interface (Command = 0F9H)

If the 8292 is not the System Controller this command acts like a NOP and flags a USER ERROR in the Error Flag Register. No TCI will occur.

If the 8292 is the System Controller then IFC is set TRUE for approximately  $100^{\circ}$  µsec and the 8292 becomes the Controller-in-Charge and asserts ATN. TCI will be set, only if the 8292 was NOT the CIC.

STCNI — Start Counter Interrupts (Command = 0FEH)

Enables the EV Counter Interrupt. TCI will not be set. Note that the counter must be enabled by a GSEC command.

SPCNI — Stop Counter Interrupts (Command = 0F0H)

The 8292 will not generate an EV interrupt when the counter reaches 0. Note that the counter will continue counting. TCI will not be set.

SREM — Set Interface to Remote Control (Command = 0F8H)

If the 8292 is the System Controller, it will set REN

and TCI TRUE. Otherwise it only sets the User Error Flag.

SLOC — Set Interface to Local Mode (Command = 0F7H)

If the 8292 is the System Controller, it will set REN FALSE and TCI TRUE. Otherwise, it only sets the User Error Flag.

EXPP — Execute Parallel Poll
(Command = 0F5H)

If not Controller-in-Charge, the 8292 will treat this as a NOP and does not set TCI. If it is the Controller-in-Charge then it sets IDY (EOI & ATN) TRUE and generates a local DAV pulse (that never reaches the GPIB because of gates in the 8293). If the 8291 is configured as a listener, it will capture the Parallel Poll Response byte in its data register. TCI is not generated, the CPU must detect the BI (Byte In) from the 8291. The 8292 will be ready to accept another command before the BI occurs; therefore the 8291's BI serves as a task complete indication.

GTSB — Go To Standby (Command = 0F6H)

If the 8292 is not the Controller-in-Charge, it will treat this command as a NOP and does not set TCI TRUE. Otherwise, it goes to Controller Standby State (CSBS), sets ATN FALSE and TCI TRUE. This command is used as part of the Send, Receive, Transfer and Serial Poll System commands (see next section) to allow the addressed talker to send data/status.

If the data transfer does not start within the specified Time-Out, the 8292 sets TOUT2 TRUE in the Error Flag Register and sets SPI (if enabled). The controller continues waiting for a new command. The CPU must decide to wait longer or to regain control and take corrective action.

GSEC — Go to Standby and Enable Counting (Command = 0F4H)

This command does the same things as GTSB but also initializes the event counter to the value previously stored in the Event Counter Register (default value is 256) and enables the counter. One may wire the count input to NDAC to count bytes. When the counter reaches zero, it sets EV (and SPI if enabled) in Interrupt Status and will set EV every 256 bytes thereafter. Note that there is a potential loss of count information if the CPU does not respond to the EV/SPI before another 256 bytes have been transferred. TCI will be set at the end of the command.

TCSY — Take Control Synchronously (Command = 0FDH)

If the 8292 is not in Standby, it treats this command as a NOP and does not set TCl. Otherwise, it waits for the proper handshake state and sets ATN TRUE. The 8292 will set TOUT3 if the handshake never assumes the correct state and will remain in this command until the handshake is proper or a RSTI command is issued. If the 8292 successfully takes control, it sets TCI TRUE.

This is the normal way to regain control at the end of a Send, Receive, Transfer or Serial Poll System Command. If TCSY is not successful, then the controller must try TCAS (see warning below).

### TCAS — Take Control Asynchronously O ton H (Command = 0FCH)

If the 8292 is not in Standby, it treats this command as a NOP and does not set TCI. Otherwise, it arbitrarily sets ATN TRUE and TCI TRUE. Note that this action may cause devices on the bus to lose a data byte or cause them to interpret a data byte as a command byte. Both Actions can result in anomalous behavior. TCAS should be used only in emergencies. If TCAS fails, then the System Controller will have to issue an ABORT to clean things up.

### GIDL — Go to Idle (Command = 0F1H) 8 3 4 1

If the 8292 is not the Controller in Charge and Active, then it treats this command as a NOP and does not set TCI. Otherwise, it sets ATN FALSE, becomes Not Controller in Charge, and sets TCI TRUE. This command is used as part of the Pass Control System Command.

# TCNTR — Take (Receive) Control (Command = 0FAH)

If the 8292 is not Idle, then it treats this command as a NOP and does not set TCI. Otherwise, it waits for the current Controller-in-Charge to set ATN FALSE. If this does not occur within the specified Time Out, the 8292 sets TOUT1 in the Error Flag Register and sets SPI (if enabled). it will not proceed until ATN goes false or it receives an RSTI command. Note that the Controller in Charge must previously have sent this controller (via the 8291's command pass through register) a Pass Control message. When ATN goes FALSE, the 8292 sets CIC, ATN and TCI TRUE and becomes Active.

### SOFTWARE DRIVER OUTLINE

The set of system commands discussed below is shown in Figure 14. These commands are implemented in software routines executed by the main CPU.

The following section assumes that the Controller is the System Controller and will not Pass Control. This is a valid assumption for 99+% of all controllers. It also assumes that no DMA or Interrupts will be used. SYC (System Control Input)

should not be changed after Power-on in any system
— it adds unnecessary complexity to the CPU's software.

In order to use polling with the 8292 one must enable TCI but not connect the pin to the CPU's interrupt pin. TCI must be readable by some means. In this application example it is connected to bit 1 port 6FH on the ZT7488/18. In addition, the other three 8292 interrupt lines and the 8291 interrupt are also on that port (SPI-Bit 2, IBFI-Bit 4, OBFI-Bit 3, 8291 INT-Bit 0).

These drivers assume that only primary addresses will be used on the GPIB. To use secondary addresses, one must modify the test for valid talk/listen addresses (range macro) to include secondaries.

Figure 14. Software Driver Routines

#### INITIALIZATION

8292 — Comes up in Controller Active State when SYC is TRUE. The only initialization needed is to enable the TCI interrupt mask. This is done by writing 0A0H to Port 68H.

8291 — Disable both the major and minor addresses because the 8291 will never see the 8292's commands/addresses (refer to earlier hardware discussion). This is done by writing 60H and 0E0H to Port 66H.

Set Address Mode to Talk-only by writing 80H to Port 64H.

Set internal counter to 3 MHz to match the clock input coming from the 8085 by writing 23H to Port 65H. High speed mode for the handshakes will not be used here even though the hardware uses threestate drivers.

No interrupts will be enabled now. Each routine will enable the ones it needs for ease of polling operation. The INT bit may be read through Port 6FH. Clear both interrupt mask registers.

Release the chip's initialization state by writing 0 to Port 65H.

INIT:

;3 MHz in this ap note example

:Releases 8291 from init. state

### TALKER/LISTENER ROUTINES

### Send Data

SEND < listener list pointer > < count > < EOS > < data buffer pointer >

This system command sends data from the CPU to one or more devices. The data is usually a string of ASCII characters, but may be binary or other forms as well. The data is device-specific.

My Talk Address (MTA) must be output to satisfy the GPIB requirement of only one talker at a time (any other talker will stop when MTA goes out). The MTA is not needed as far as the 8291 is concerned it will be put into talk-only mode (ton).

This routine assumes a non-null listener list in that it

always sends Universal Unlisten. If it is desired to send data to the listeners previously addressed, one could add a check for a null list and not send UNL. Count must be 255 or less due to an 8 bit register. This routine also always uses an EOS character to terminate the string output; this could easily be eliminated and rely on the count. Items in brackets () are optional and will not be included in the actual code in Appendix A.

#### Receive Data

RECV < talker > < count > < EOS > < data buffer pointer >

This system command is used to input data from a device. The data is typically a string of ASCII characters.

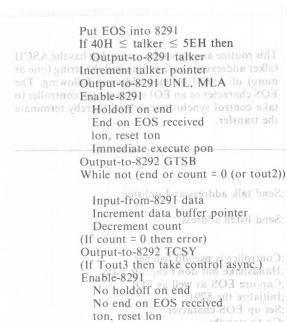

This routine is the dual of SEND. It assumes a new talker will be specified, a count of less than 257, and an EOS character to terminate the input. EOI received will also terminate the input. Figure 15 shows the flow chart for the RECV ending conditions. My Listen Address (MLA) is sent to keep the GPIB transactions totally regular to

facilitate analysis by a GPIB logic analyzer like the Ziatech ZT488. Otherwise, the bus would appear to have no listener even though the 8291 will be listening.

Note that although the count may go to zero before the transmission ends, the talker will probably be left in a strange state and may have to be cleared by the controller. The count ending of RECV is therefore used as an error condition in most situations.

Figure 18. XFER from " \" to "1", "2", "+"; EOS = 0DH

This system command is used to transfer data from a talker to one or more listeners where the controller does not participate in the transfer of the ASCII data. This is accomplished through the use of the 8291's continuous acceptor handshake mode while in listen-only.

This routine assumes a device list that has the ASCII talker address as the first byte and the string (one or more) of ASCII listener addresses following. The EOS character or an EOI will cause the controller to take control synchronously and thereby terminate the transfer. bovisos 203 no ball

## Parallel Poll Disable

PPDS < listener list >

This system command disables one or more devices from responding to a Parallel Poll by issuing a Parallel Poll Disable (PPD). It does not deconfigure the devices. As possess between no matters shift

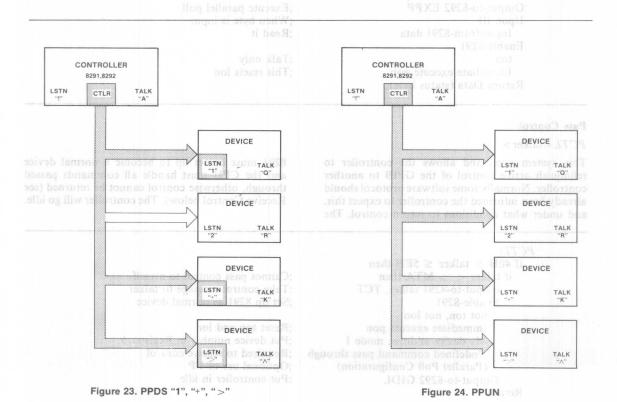

will still be set when the next Pacally Poll occurs.
This command recent the byte SQAP is. Output-to-8291 UNL brismmos and T While  $20H \le Listener \le 3EH$ Output-to-8291 listener Increment listener list pointer Output-to-8291 PPC, PPD/Ino notal 1 Return

;Universal Unlisten

;Check for valid listener

:Address listener

;Disable PP on all listeners

#### Parallel Poll Unconfigure

#### PPUN

This system command deconfigures the Parallel Poll response of all devices by issuing a Parallel Poll Unconfigure message.

#### PPUN:

Output-to-8291 PPU Return

#### :Unconfigure all parallel poll

#### Conduct a Parallel Poll

## Parallel Poll Disable (PPD). It does not JOSA

This system command causes the controller to conduct a Parallel Poll on the GPIB for approximately 12.5 usec (at 6 MHz). Note that a parallel poll does not use the handshake; therefore, to ensure that the device knows whether or not its positive response was observed by the controller, the CPU should explicitly acknowledge each device by a devicedependent data string. Otherwise, the response bit will still be set when the next Parallel Poll occurs. This command returns one byte of status.

#### PPOL:

Enable-8291

Output-to-8292 EXPP

Upon BI

Input-from-8291 data

Enable-8291

Immediate execute pon Return Data (status byte) Output-to-8291 PPC, PPLylno notice.

This resets ton

Execute parallel poll

;When byte is input

:Read it

:Talk only

;This resets lon

#### Pass Control

#### PCTL < talker >

This system command allows the controller to relinquish active control of the GPIB to another controller. Normally some software protocol should already have informed the controller to expect this, and under what conditions to return control. The 8291 must be set up to become a normal device and the CPU must handle all commands passed through, otherwise control cannot be returned (see Receive Control below). The controller will go idle.

#### PCTL:

If  $40H \le talker \le 5EH$  then if talker < > MTA then output-to-8291 talker, TCT

Enable-8291

not ton, not lon

Immediate execute pon

;Take control message to talker

Set up 8291 as normal device

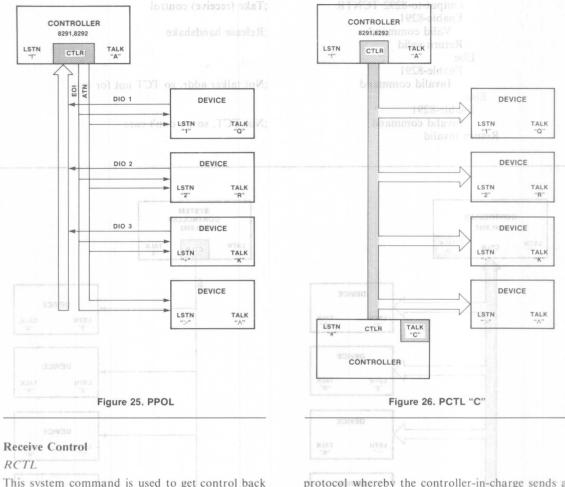

:Reset ton and lon

;Put device number in Register 6

Required to receive control

:Optional use of PP

;Put controller in idle

This system command is used to get control back from the current controller-in-charge if it has passed control to this inactive controller. Most GPIB systems do not use more than one controller and therefore would not need this routine.

To make passing and receiving control a manageable event, the system designer should specify a

protocol whereby the controller-in-charge sends a data message to the soon-to-be-active controller. This message should give the current state of the system, why control is being passed, what to do, and when to pass control back. Most of these issues are beyond the scope of this Ap Note.

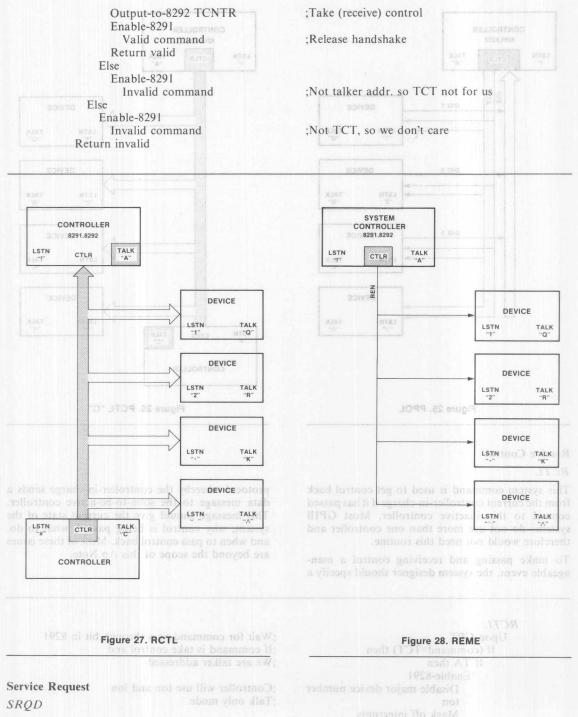

```
RCTL:
Upon CPT
If (command=TCT) then
If TA then
Enable-8291
Disable major device number ton
Mask off interrupts
Immediate execute pon
```

;Wait for command pass through bit in 8291 ;If command is take control and

;We are talker addressed

;Controller will use ton and lon ;Talk only mode

This system command is used to detect the occurrence of a Service Request on the GPIB. One or

This system command is used to detect the occurrence of a Service Request on the GPIB. One or more devices may assert SRQ simultaneously, and

the CPU would normally conduct a Serial Poll after calling this routine to determine which devices are SRQing.

SROD: If SRQ then :Test 92 status bit Output-to-8292 IACK.SRQ ;Acknowledge it Return SRO Else return no SRQ SYSTEM CONTROLLER Remote Enable REMEremote until they are later addressed to listen by This system command asserts the Remote Enable line (REN) on the GPIB. The devices will not go some other system command. #### Interface Clear/Abort

**IFCL** 

This system command asserts the GPIB's Interface Clear (IFC) line for at least 100 microseconds. This causes all interface logic in all devices to go to a known state. Note that the device itself may or

may not be reset, too. Most instruments do totally reset upon IFC. Some devices may require a DCLR as well as an IFCL to be completely reset. The (system) controller becomes Controller-in-Charge.

IFCL:
Output-to-8292 ABORT
Return

;8292 asserts Interface Clear :For 100 microseconds

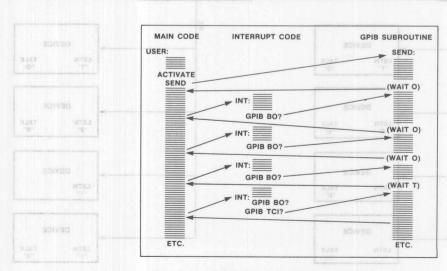

#### INTERRUPTS AND DMA CONSIDERATIONS

The previous sections have discussed in detail how to use the 8291, 8292, 8293 chip set as a GPIB controller with the software operating in a polling mode and using programmed transfer of the data. This is the simplest mode of use, but it ties up the microprocessor for the duration of a GPIB transaction. If system design constraints do not allow this, then either Interrupts and/or DMA may be used to free up processor cycles.

The 8291 and 8292 provide sufficient interrupts that one may return to do other work while waiting for such things as 8292 Task Completion, 8291 Next Byte In, 8291 Last Byte Out, 8292 Service Request

In, etc. The only difficulty lies in integrating these various interrupt sources and their matching routines into the overall system's interrupt structure. This is highly situation-specific and is beyond the scope of this Ap Note.

The strategy to follow is to replace each of the WAIT routines (see Appendix A) with a return to the main code and provide for the corresponding interrupt to bring the control back to the next section of GPIB code. For example WAITO (Wait for Byte Out of 8291) would be replaced by having the BO interrupt enabled and storing the (return) address of the next instruction in a known place. This co-routine structure will then be activated by a BO interrupt. Fig. 31 shows an example of the flow of control.

1071 66 Stuffigure 31. GPIB Interrupt & Co-Routine Flow of Control . 65 Stup 13

DMA is also useful in relieving the processor if the average length of a data buffer is long enough to overcome the extra time used to set up a DMA chip. This decision will also be a function of the data rate of the instrument. The best strategy is to use the DMA to handle only the data buffer transfers on SEND and RECV and to do all the addressing and control just as shown in the driver descriptions.

Another major reason for using a DMA chip is to increase the data rate and therefore increase the overall transaction rate. In this case the limiting factor becomes the time used to do the addressing and control of the GPIB using software like that in Appendix A. The data transmission time becomes insignificant at DMA speeds unless extremely long buffers are used.

Refer to Figure 11 for a typical DMA and interrupt based design using the 8291, 8292, 8293. A system we like this can achieve a 250K byte transfer rate while under DMA control.

## APPLICATION EXAMPLE TS no sess, 1858 1911

This section will present the code required to operate a typical GPIB instrument set up as shown in Fig. 32. The HP5328A universal counter and the HP3325 function generator are typical of many GPIB devices; however, there are a wide variety of software protocols to be found on the GPIB. The Ziatech ZT488 GPIB analyzer is used to single step the bus to facilitate debugging the system. It also serves as a training/familiarization aid for new-comers to the bus.

This example will set up the function generator to each terms output a specific waveform, frequency and ampli-

tude. It will then tell the counter to measure the frequency and Request Service (SRQ) when complete. The program will then read in the data. The assembled source code will be found at the end of Appendix A.

#### and conclusion of CONCLUSION of the of the

This Application Note has shown a structured way to view the IEEE 488 bus and has given typical code sequences to make the Intel 8291, 8292, and 8293's behave as a controller of the GPIB. There are other ways to use the chip set but whatever solution is chosen, it must be integrated into the overall system software

0023

The ultimate reference for GPIB questions is the IEEE Std 488, -1978 which is available from IEEE. 345 East 47th St., New York, NY, 10017. The ultimate reference for the 8292 is the source listing for it (remember it's a pre-programmed UPI-41A) which is available from INSITE. Intel Corp., 3065 Bowers Ave., Santa Clara, CA 95051.

# TEST CASES FOR THE SOFTWARE DRIVERS

The following test cases were used to exercise the software routines and to check their action. To provide another device/controller on the GPIB a ZT488 GPIB Analyzer was used. This analyzer

acted as a talker, listener or another controller as needed to execute the tests. The sequence of outputs are shown with each test. All numbers are hexadecimal.
